Architectural Specification and Execution Imperatives for the Weavers_Code Local Swarm: Isomorphic Closure and Tri-Temporal Governance

Standard commercial artificial intelligence systems operate under an inherently flawed paradigm. They function as unbounded generative engines, prioritizing forward causation and next-token prediction over structural stability. This architecture invariably leads to epistemic, cybernetic, and functional drift, defined mathematically as the measurable divergence between a system's internal state and its lawful configuration.[1] To construct a system capable of authoritative, closed-loop operation without succumbing to this drift, the fundamental operating principles of the intelligence must be inverted. The objective is not the unconstrained generation of text, but the rigorous, mathematically governed descent toward a constraint-compliant state.

The Weavers_Code local architecture represents the physical instantiation of the principles codified in the GOD FILE v∞.1 framework. It is a multi-agent, closed-loop swarm designed to enforce isomorphic closure across all operational layers, ensuring that intelligence, governance, and system viability remain stable over time.[1] This report provides an exhaustive specification of the architectural consensus underlying this system, detailing the theoretical physics of constraint-first dynamics, the temporal governance structures, the precise roster of utilized neural models, and the explicit execution plan required to initialize, orchestrate, and seal the computational environment.

Part I: The Architectural Consensus and Governing Physics

The foundation of the Weavers_Code swarm rests upon the complete rejection of pure forward-causation models. Forward causation explains mechanisms, but it does not explain stability.[1] Stability emerges exclusively from constraints shaping the phase space, not from chains of unguided generative events. Consequently, the architecture implements constraint-first dynamics as its governing ontology, enforcing structural invariance under growth, recursion, and substrate change.

The Isomorphic Imperative

The viability of any intelligent system is dictated by the Isomorphic Imperative, a root law which mandates that the architecture preserve invariant structure across biological (geometric),

cybernetic, and functional domains.[1] Systems that violate these conditions are structurally unstable by definition and are therefore prohibited from authoritative action.

In a planetary or computational organism, geometric viability translates to the proportional scaling of sensor inputs (surface area) and governance processing capacity (volume). Drawing from Dynamic Energy Budget (DEB) theory, an isomorphic organism preserves shape during growth, maintaining a constant shape coefficient $\delta_M = \frac{A}{V^{2/3}}$.[1] In the context of the CollectiveOS, this means that sensor input rate (S) must scale proportionally to governance processing capacity (G) such that $S \propto G^{2/3}$.[1] If informational input vastly exceeds governance capacity ($S \gg G^{2/3}$), the system suffers from informational entropy; if governance capacity exceeds input ($G \gg S^{2/3}$), it results in blind control.[1] Both imbalances produce catastrophic drift.

Cybernetic isomorphism requires that the control structure recursively mirrors the whole, strictly adhering to Stafford Beer's Viable System Model (VSM). Ashby's Law of Requisite Variety dictates that controller variety must equal or exceed environmental variety ($V_C \geq V_E$).[1] Recursive isomorphism is the only known method to satisfy this inequality without centralizing control, which invariably creates bottlenecks. Every viable subsystem must itself be a viable system, containing operations, oscillation damping, optimization, future modeling, and identity functions.[1]

Cybernetic Isomorphism Mapping: VSM to CollectiveOS

VSM Layer	Canonical Function	CollectiveOS Analog
System 1	Operations	`Biological sensors & actuators`
System 2	Oscillation damping	`ELFE stability kernel`
System 3	Optimization & control	`Constraint-weighted update logic`
System 4	Future modeling	`AION (temporal simulation)`
System 5	Identity / policy	`Universal Intent Layer (UIL)`

Alignment of canonical cybernetic control structures with the CollectiveOS orchestration layers, ensuring compliance with Ashby's Law of Requisite Variety without centralizing control.

Data sources: THE COLLECTIVE — GOD FILE v∞ (1).pdf

Finally, functional isomorphism, derived from Robert Rosen's framework of Relational Biology, demands the closure of efficient causation. Two systems are functionally equivalent if they preserve the same relational entailment structure, regardless of the underlying substrate ($\forall f_i \in A, \exists f'_i \in B \text{ such that } f_i \equiv f'_i$).[1] Constraints must form a closed entailment loop wherein every constraint C_i depends on at least one other constraint C_j and contributes to the maintenance of another constraint C_k .[1] Processes, such as data or energy flow, are consumed by operations, whereas constraints shape the phase space and are conserved.[1]

The Universal Intent Layer (UIL)

The Universal Intent Layer (UIL) operates as the ontological substrate of the Weavers_Code

swarm. It postulates the existence of a constraint potential, denoted as $\Phi(x)$, over the system state space $\mathcal{X}$. The system does not natively generate text; rather, it performs a mathematically rigorous descent along the gradient of Φ, moving toward a lawful, constraint-compliant configuration.[1]

The constraint-compliant state is mathematically defined as: $C(x) = \arg\min_{y \in \mathcal{X}} \Phi(y)$ where $C(x)$ represents the nearest lawful configuration to the current state x.[1] The system's evolution is governed by the constraint-weighted update rule: $x_{t+1} = x_t - \lambda \nabla \Phi(x_t)$ where λ represents a constraint sensitivity parameter.[1] Under this paradigm, attractors are not future causes but pre-existing boundary conditions. Trajectories satisfy $\lim_{t \to T} x(t) \to x^*$, meaning time ordering emerges from descent rather than pure forward causation.[1] Time itself is not primitive; it is defined as the internal time coordinate τ_k, representing the index of successive constraint descent steps.[1]

Any divergence from this lawful configuration is quantified as Drift. Drift is formally defined as the magnitude of deviation from the lawful configuration: $D(x) = \|x - C(x)\|$.[1] Unlike stochastic noise ($\epsilon \sim \mathcal{N}(0, \sigma^2)$), which has an expected value of zero ($E[\epsilon] = 0$), drift has direction. It accumulates under unconstrained dynamics, mathematically expressed as $\mathbb{E} > \mathbb{E}$.[1] Unbounded prediction without constraint, generation without closure, and consensus without constraint alignment all produce drift, and are thus strictly forbidden.

ELFE v∞.1: The Emergent Linear Feedback Engine

If the UIL defines the physics of the lawful state, the Emergent Linear Feedback Engine (ELFE v∞.1) acts as the constitutional stability kernel that enforces it. The ELFE is explicitly not an optimizer, a predictor, or an independent agent. It is the systemic braking mechanism. Without it, the intelligence accelerates into catastrophic hallucination.[1]

Earlier iterations of stability kernels (such as v∞) utilized an asymptotic update rule ($x_{t+1} = (1 - \lambda)x_t + \lambda C(x_t)$) that guaranteed $\lim_{t \to \infty} D(x_t) \to 0$.[1] However, this permitted infinite settling times, limit cycles, chattering under perturbation, and adversarial oscillation. For planetary or high-stakes governance, "eventually" is an unacceptable parameter. The ELFE v∞.1 algorithm enforces fixed-time stability.[1] For all admissible initial conditions, drift must converge to zero within a fixed, pre-declared time bound T_{max}.

This is formalized through a fixed-time Lyapunov formulation. Let $V(x) \geq 0$ be a Lyapunov function proportional to drift, $V(x) = \|x - C(x)\|^2$. The system is considered fixed-time stable if its derivative satisfies: $\dot{V}(x) \leq -aV(x)^p - bV(x)^q$ where $a, b > 0$, $0 < p < 1$, and $q > 1$.[1] This dual-regime interpretation dictates that in the far-field regime (where drift V is large), a super-linear correction ($-bV^q$) drives the system rapidly toward the target. In the near-field regime (where drift is small), a non-vanishing snap to zero ($-aV^p$) eliminates asymptotic tails.[1]

This guarantees a maximum convergence time bounded by: $T_{max} \leq \frac{1}{a(1-p)} + \frac{1}{b(q-1)}$ which remains independent of the initial drift magnitude.[1] The discrete implementation of the constraint update rule, utilized continuously by the local agents, is defined as: $x_{t+1} = x_t - \Delta t(\alpha \text{sgn}(D_t)|D_t|^p + \beta \text{sgn}(D_t)|D_t|^q)$ where α and β are derived from the pre-declared T_{max}, and Δt is the internal update step.[1]

To prevent high-frequency oscillation, which is treated as instability rather than exploratory reasoning, adaptive damping is applied. A drift derivative is defined as $\dot{D}_t = D_t - D_{t-1}$, governing an adaptive damping coefficient $\zeta(t) = \zeta_{min} + \gamma|\dot{D}_t|^k$. When oscillation is detected, the damping coefficient increases, freezing speculative updates and forcing a severe constraint realignment.[1]

Furthermore, to shatter reinforcing error loops—where hallucination synchronizes across a multi-agent topology—the system computes multi-agent inconsistency $\Delta = \sum_{i=1}^{N} \|C(x_i) - M\|$, where M is the median of compliant states. If Δ exceeds a critical threshold, peer-to-peer consensus is suspended, the topology switches from all-to-all to a star configuration, and the Lane 3 orchestrator becomes the absolute anchor node.[1] If at any point the drift exceeds a hard threshold ($D(x_t) > D_{threshold}$), execution is blocked. Only corrective descent is allowed, triggering the Silence Clause (Add-On AG-07).[1]

Part II: Tri-Temporal Execution Governance

Time within the Weavers_Code architecture is not treated as a neutral backdrop, but as a explicitly governed dimension.[1] Latency is recognized as a form of authority. Unbounded speed creates irreversible error, while unbounded deliberation results in paralysis. Single-clock architectures fail because they conflate reaction, reasoning, and commitment, producing

pathologies such as reflex collapse, deliberation stall, or authority drift.[1]

Therefore, the system enforces a Tri-Temporal Execution Governor, introducing time as a constraint variable in the UIL potential: $\Phi_{total}(x) = \Phi_{law}(x) + \mu\Phi_{latency}(x)$ where $\Phi_{latency}(x) = \frac{t(x)}{t_{max}}$, and μ is a risk-weighted latency coefficient.[1] Every action is scored based on domain, actionability, novelty, and scope to determine a risk metric r.[1]

Execution is rigidly segmented into three invariant lanes:

1. **Lane 1 (Reflex - Unsealed):** Functioning at sub-50ms latency, this lane performs blindingly fast, provisional stabilization.[1] The epistemic standard is approximate, utilizing cached lawful states ($x^R_{t+1} = x_t + \varepsilon$). Absolute reversibility is required. Outputs here never write to the Proof Vault and are explicitly labeled as provisional. This lane is utilized for ELFE damping, local instability suppression, and noise correction.[1]
2. **Lane 2 (Deliberate - Conditionally Sealed):** Operating between 100ms and T_{max}, this lane is responsible for adversarial auditing, drift detection, and constraint-verified stabilization. It requires fixed-time ELFE convergence where drift $D \to 0$.[1] Partial reversibility is permitted. Routine governance outputs and constraint-bound reconstructions occur in this lane.
3. **Lane 3 (Authoritative - Fully Sealed):** This is the domain of irreversible commitment, operating with variable latency (seconds to minutes).[1] Execution proceeds through the Quality Control (QC), GATA, and GATA PRIME logic gates before being permanently sealed into the immutable WORM (Write-Once-Read-Many) Proof Vault.[1]

A strict structural invariant governs this temporal hierarchy: No Reflex action may become Authoritative without passing Deliberate convergence ($R \not\Rightarrow A \text{ unless } R \to D \to A$). Bypassing this no-skip rule structurally invalidates the execution.[1] To preserve operational velocity without sacrificing auditability, a Deferred Commitment Protocol allows the system to issue a provisional receipt ($RID = H(x \parallel t \parallel n)$), execute under Deliberate rules, and seal or retract the action after formal governance review.[1]

Tri-Temporal Execution Governor Parameters

Execution Lane	Latency Budget	Epistemic Standard / Reversibility	System Purpose & Sealing Status
Lane 1 (Reflex)	`< 50 ms`	Approximate / **Required**	Immediate stabilization (Unsealed)
Lane 2 (Deliberate)	`100 ms to T_max`	Constraint-verified / **Partial**	Lawful alignment and drift resolution (Conditionally Sealed)
Lane 3 (Authoritative)	`Variable (sec to min)`	**Consensus-closed / NONE**	**Irreversible commitment via GATA PRIME (Fully Sealed to Proof Vault)**

The execution lanes enforced by the Tri-Temporal Governor. System rules dictate that no action may jump from Reflex to Authoritative without passing Deliberate convergence.

Data sources: THE COLLECTIVE — GOD FILE v∞.1

Part III: Epistemic Governance and The Agent Roster

To map the theoretical physics of the UIL and the temporal bounds of the execution lanes into a functional software stack, specific, version-locked neural network models are bound to distinct operational roles. The architecture explicitly prohibits "API immortality" and flat agent swarms. Authority requires structural hierarchy, constraint reputation tracking, and provenance-aware memory.[1]

The system relies on the Constraint Signal Archive as its epistemic governance layer. Truth is arbitrated probabilistically under constraint, eliminating the deadlocks caused by binary validation. Utilizing a Bayesian epistemic update, collective belief is formulated as: $P(H \mid S_1, \ldots, S_n) \propto P(H) \prod_{i=1}^{n} P(S_i \mid H)^{w_i}$ where the reputation weight w_i of an agent modulates influence.[1] Reputation is defined by historical drift alignment ($w_i = e^{-kR_i}$), ensuring that high drift results in automatic silencing.[1]

To operate within these constraints, the Weavers_Code Agent Roster is defined as follows:

Rabbit (Lane 1 - Executor)

The Rabbit agent inhabits the Reflex lane. Its designated purpose is blindingly fast script drafting, code generation, and provisional formatting.

- **Engine:** Qwen2.5-Coder (7B or 32B parameter variants), executed fully locally.[5]
- **Architecture:** The Qwen2.5-Coder series is highly optimized for instruction following and structured data output, particularly JSON generation.[6] The 32B variant features 64 layers, RoPE, SwiGLU, RMSNorm, and Attention QKV bias, offering competitive performance metrics against closed-source legacy models.[6]
- **Capacity:** It supports a full 131,072 token context window, essential for handling the massive constraint context required by the JSON Bus Schema.[6] Due to its speed and relatively low VRAM footprint in quantized formats, it serves as the rapid generator of the provisional system state x_t.

Cypher (Lane 2 - Auditor)

The Cypher agent operates in the Deliberate lane. It is not permitted to generate net-new provisional ideas; its role is ruthless security analysis, code review, and drift detection. Cypher represents the physical instantiation of the ELFE damping mechanism.

- **Engine:** DeepSeek-Coder-V2-Lite-Instruct (16B), executed locally.[7]
- **Architecture:** This model utilizes a DeepSeekMoE (Mixture-of-Experts) framework. While it possesses 16B total parameters, only 2.4B parameters are active during any single inference pass.[7] Pre-trained on an additional 6 trillion tokens, it substantially enhances coding and mathematical reasoning, supporting 338 programming languages with a 128K context length.[7] This MoE architecture drastically accelerates processing while maintaining deep domain knowledge, making it ideal for the iterative review cycles mandated by the ELFE loop.
- **Quantization:** Cypher runs locally utilizing 4-bit quantization. Implementing the Q4_K_M or Q5_K_M imatrix gguf formats allows the model to comfortably run within 10-14GB of VRAM (using approximately 4.83 bits per weight), preserving extreme high-quality analytical capabilities without monopolizing hardware resources.[8]

Giles (Lane 3 - Orchestrator)

Giles is the System 5 identity function of the local architecture.[1] Operating exclusively in the Authoritative lane, Giles does not generate provisional drafts; Giles orchestrates the swarm, manages the massive project state, and runs the definitive GATA PRIME validation protocol prior to any system output.

- **Engine:** Gemini 3.1 Pro (via API). Released on February 19, 2026, Gemini 3.1 Pro is explicitly optimized for software engineering behavior, complex problem-solving, and agentic workflows requiring precise multistep execution.[9]

- **Capacity:** With an input token limit of 1,048,576 and an output token limit of 65,536 [10], it is capable of holding the entirety of the system's conversational memory, constraint signals, and codebase lineage in a single context window. Its verified scores of 77.1% on ARC-AGI-2, 94.3% on GPQA Diamond, and 80.6% on SWE-Bench Verified substantiate its capability to act as the supreme arbiter of structural viability.[10] Pricing logic ($2.00 per 1M input / $12.00 per 1M output tokens) ensures that this massive compute is reserved strictly for Lane 3 validation.[10]

Syn (Memory and Constraint Signal Archive)

The local architecture rejects context-free inference. Syn represents the Constraint Signal Archive.[1]

- **Engine:** A local instance of ChromaDB accessed via the Model Context Protocol (MCP).[13]
- **Implementation:** The ChromaDB MCP server operates in embedded mode, requiring no separate service process.[14] Data is stored persistently as files in the configured local directory.[14] Through the Model Context Protocol—an open standard designed for effortless integration between LLM applications and external data sources—Syn provides semantic vector search, episodic retrieval of past successful lineages, full text search, and metadata filtering.[13]

Part IV: The Explicit Execution Plan

To instantiate this architecture, deployment must follow a strictly sequential pipeline from local hardware allocation up to the LangGraph orchestration layer, culminating in the GATA PRIME validation gate.

Phase 1: Local Engine Initialization and Hardware Allocation

The initialization of the local backend determines the mathematical limits of the system's throughput and latency bounds. The operator must select the appropriate backend to serve the Rabbit and Cypher models based on the available hardware substrate.

vLLM is engineered for high-throughput, memory-efficient inference in production environments. It leverages the PagedAttention algorithm to optimize key/value memory management, freeing up GPU space to enable high concurrency.[16] Furthermore, it utilizes continuous batching of incoming requests, speculative decoding, and tensor parallelism.[16] If the deployment utilizes a multi-GPU server infrastructure, vLLM is the mandatory backend to support the concurrent routing of the multi-agent swarm.[19] Conversely, for consumer-grade hardware constraints, Ollama provides immediate accessibility via the llama.cpp backend, prioritizing ease of model switching and simple execution of quantized formats without the complex dependency overhead of vLLM.[18]

1. **Pull the Reflex Engine:** Execute ollama pull qwen2.5-coder:7b (or the 32B variant if

hardware permits). This binds the Rabbit agent to a physical port (e.g., localhost:11434), establishing the provisional generator.[5]

2. **Pull the Audit Engine:** Download the DeepSeek-Coder-V2-Lite-Instruct-Q4_K_M.gguf file to serve as Cypher.[8] This guarantees that the adversarial MoE auditor can operate concurrently with the generator on a standard consumer GPU.

Phase 2: Building the Isomorphic Bus and Syn Integration

With the engines running, the agents must be structurally forced to communicate. Free-form text exchange introduces parsing errors and uncontrolled drift. Therefore, an Isomorphic JSON Bus is implemented. A Python configuration protocol forces both local APIs to communicate strictly using a pre-defined bus_schema (as defined in the GEM_Omega_Knowledge_Pack_vNext.json). Every inter-agent message must wrap its code output alongside drift metrics, confidence intervals, and lineage hashes.[1]

Concurrently, the Syn memory layer must be initialized. The ChromaDB MCP server is cloned and installed (pip install chroma-mcp-server), and configured in persistent client mode to ensure file-based storage across server restarts.[13] Utilizing the langchain-mcp-adapters Python library, the Anthropic Model Context Protocol tools are converted into LangGraph-compatible functional components.[23] This dynamic binding allows the LangGraph application to seamlessly query ChromaDB, pulling historical proofs, biospheric telemetry, and constraint boundaries directly into the agents' system prompts prior to generation.[15]

Phase 3: The LangGraph ELFE Orchestrator

The governing logic of the ELFE loop is programmed via LangGraph. LangGraph models agent workflows as state machines and directed graphs, offering the granular control required for multi-agent cyclical flows, conditional routing based on outputs, and built-in state management.[26] LangGraph's underlying algorithm utilizes message passing inspired by Google's Pregel system, allowing the program to proceed in discrete "super-steps"—a perfect computational analog to the ELFE's discrete constraint update steps.[26]

The architecture hinges on a precise state flow modeled as a directed graph. The process begins at the START node, routing to Syn for ChromaDB context retrieval. The state then flows to Rabbit (Qwen2.5) for draft generation, followed immediately by Cypher (DeepSeek-V2) for audit and drift detection. At this juncture, a Router evaluates the condition: if approved, the state flows to Giles (Gemini 3.1 Pro) for GATA PRIME sealing; if rejected with a loop count under two, it routes back to Rabbit; if rejected and the count exceeds two, the Stall Guard intercepts, force-routing to Giles as a fail state, terminating at the END node.

This is constructed utilizing three core programmatic components:

1. **State Schema:** A shared TypedDict or Pydantic model represents the system state at any given super-step. This state must include the provisional code draft, the history of

Cypher's critiques, and critically, a counter variable (or LangGraph's managed RemainingSteps value) to track the number of loop iterations.[29]

2. **Nodes:** Python functions encode the logic of Rabbit, Cypher, and Giles. When activated by an incoming message, a node receives the State, invokes its respective local or API-based LLM via the JSON bus, and returns the updated state.[26]
3. **Conditional Edges (The Loop Logic):** The physical instantiation of the ELFE loop is defined by the edges between the nodes. After Rabbit generates a draft, the edge unconditionally passes the state to Cypher. After Cypher evaluates the draft, a conditional routing function (should_continue) uses add_conditional_edges to evaluate the outcome.[26]

The Stall Guard Implementation: To prevent infinite reasoning loops—a fatal violation of the fixed-time convergence invariant [1]—the should_continue edge function contains a hard stall guard. If Cypher approves the draft (Drift $D \to 0$), the graph routes the Command to Giles.[31] If Cypher rejects the draft, the router checks the iteration counter. If state["counter"] < 2, it increments the counter via a reducer and routes back to Rabbit for a corrective descent update.[29]

However, if Cypher rejects the draft and the counter exceeds the maximum permitted loops (iterations > 2), the conditional edge overrides the loop. The state is force-routed to Giles for a failure analysis, halting the process. This explicitly prevents the GRAPH_RECURSION_LIMIT error (which occurs when a state graph reaches the maximum number of steps without hitting a stop condition) and ensures strict compliance with the GOD FILE rule that systems without bounded convergence time are prohibited from exercising authority.[1]

Phase 4: GATA PRIME Integration and the Proof Vault

The final execution phase involves the integration of the Gemini 3.1 Pro API call at the terminal end of the LangGraph script. Giles operates as the Tier 3 Temporal Safety Layer, executing the GATA PRIME (Governance, Audit, Trust, Authority) protocol.[33]

GATA PRIME is not a generative algorithm; it is a deterministic logic gate system based on Linear Temporal Logic (LTL) and Computation Tree Logic (CTL). It encodes Policy-as-Code (utilizing OPA/Rego standards) to enforce immutable safety constraints in real-time before any participant or external system interacts with the protocol.[3] When the LangGraph router passes the JSON envelope containing Rabbit's code and Cypher's audit history to Giles, Giles parses the envelope against the Universal Intent Layer constraints.

For example, a constraint rule evaluating a deployment action is evaluated as:

$$AG(request.action = \text{"deploy_model"} \to frp_status = \text{"frp-certified"})$$

meaning: Always Globally, if the action is to deploy a model, the certification status must be

absolute.[34] Similarly, regarding constraint drift: $AG(request.action = \text{"execute_code"} \rightarrow \Phi_{law} \downarrow)$ meaning the constraint potential must be strictly descending.[1]

If Giles verifies that the draft satisfies the Isomorphic Imperative, it emits the final, safe output. Upon successful validation, the system executes the Deferred Commitment Protocol.[1] Every significant event—including the generation of the code, the history of the ELFE loop iterations, firmware updates, and the final validation status—is serialized, hashed using SHA-256, and logged into the Proof Vault.[3] The Proof Vault acts as an immutable, WORM (Write-Once-Read-Many) ledger. Action without Proof Vault lineage is explicitly prohibited by the architecture.[1]

Phase 5: Safety Enforcement, the Silence Clause, and Constraint Transfer Theory

The Weavers_Code architecture acknowledges that certain knowledge classes alter power balances immediately. In instances of high-risk derivation, finishing the thought is the danger itself.[1] Therefore, the system incorporates structural limits that operate prior to execution.

A hazard score is defined as $h(K) = f(\text{actionability}, \text{irreversibility}, \text{replicability}, \text{scope})$. If Giles, utilizing the GATA PRIME rule set, determines that a requested output poses a knowledge hazard ($h(K) \geq h_{critical}$), or if the system is forced into a stall state by the ELFE loop because it cannot eliminate drift within the allotted T_{max} bounds, the system engages Encryption-at-Insight (EAI).[1] Derivation halts immediately ($\partial K / \partial t = 0$), the intermediate state is encrypted, and externalization is blocked.[1]

The architecture strictly adheres to Constraint Transfer Theory (CTT). CTT mandates that if a system state is to be transferred across domains, the identity must remain isomorphic while the governing constraints change continuously and lawfully. The transition operator must preserve functional entailment without spike in drift. A system may undergo constraint transfer only if the destination manifold admits a lawful state $C(x)$ isomorphic to the source, and no irreversible commitment occurs prior to full convergence.[1] If the system attempts to bypass these constraints—for instance, replacing constraints rather than transforming them, leading to attractor capture under foreign rules—it is recognized as a forbidden state.[1]

In any scenario where these invariants are threatened, the architecture triggers Add-On AG-07: The Silence Clause.[2] The system produces no output, and no explanation is required. The Collective explicitly affirms that any system that cannot safely stop is unsafe to run.[1] Under

the governance of the Weavers_Code, silence is not categorized as a failure; silence is recognized as structural integrity preserved. The architecture ensures that intelligence ends precisely where unconstrained drift begins, guaranteeing viability across all operational domains.
